Abstract

1 Introduction

The seasonal timing of tree leaf production in dry deciduous savannas directly influences ecosystem processes and structure (). Leaf Area Index (LAI), leaf area per unit ground area, is tightly coupled with photosynthetic activity and therefore Gross Primary Productivity (GPP) (). Directional shifts in GPP influence the accumulation rate of woody biomass, and affect the delicate balance between tree and grass co-occurrence in these ecosystems (), with potential consequences for transition between closed-canopy forest and open savanna. From a conservation perspective, deciduous savannas with a longer growth period support a greater diversity and abundance of wildlife, particularly bird species but also browsing mammals (). Extreme weather patterns as a result of climate change are leading to shorter but more intense leaf production cycles in these ecosystems which exist at the precipice of their climatic envelope, with severe negative consequences for biodiversity (). Understanding the determinants of seasonal patterns of tree leaf production (land-surface phenology) in dry deciduous savannas can provide valuable information on spatial variation in vulnerability to climate change, and help to model their contribution to land surface models under climate change.

Previous studies have shown that diurnal temperature variation and precipitation are the primary determinants of tree phenological activity in water-limited savannas (). At regional spatial scales, savanna phenological activity can be predicted well using only climatic factors and light environment (Adole, Dash, and Atkinson, 2018), but local variation exists in leaf production cycles which cannot be attributed solely to abiotic environment (). It has been repeatedly suggested that information on biotic environment play a larger role in predicting land-surface phenology (), but implementation is most often limited to coarse ecoregions or functional vegetation types (), which lack the fine-scale resolution which can now be paired with state-of-the-art earth observation data.

Tree species vary in their life history strategy regarding the timing of leaf production (). More conservative species (i.e. slower growing, robust leaves, denser wood) tend to initiate leaf production (green-up) before rainfall has commenced, and persist after the rainy season has finished, despite having lower overall GPP, while more resource acquisitive species and juvenile individuals tend to green-up during the rainy season, and create a dense leaf-flush during the mid-season peak of growth (). It has been suggested that this variation in leaf phenological activity between species is one aspect by which increased tree species richness causes an increase in ecosystem-level productivity in deciduous savannas (). Building on research linking biodiversity and ecosystem function, one might expect that an ecosystem with a greater diversity of tree species might be better able to maintain consistent leaf coverage for a longer period over the year, as species vary in their optimal growing conditions due to niche complementarity, whereby coexisting species vary in their occupation of niche space due to competitive exclusion ().

In the water-limited savannas such as those found in large areas of southern Africa (), the ability of conservative tree species to maintain consistent leaf coverage in the upper canopy strata over the growing season, but particularly at the start and end of the growing season, may provide facilitative effects to other tree species and juveniles occupying lower canopy strata that are less

well-adapted to moisture-limiting conditions, but are more productive, by providing shade and influencing below ground water availability through hydraulic lift ().

Variation in tree species composition, as well as species richness, is also expected to have an effect on savanna phenology in southern Africa. Savannas of a number of different types (species composition and structure) are found across southern Africa, but these are often poorly differentiated in regional-scale phenological studies (), resulting in a dearth of information on the phenological behaviour of different woodlands. As our ability to remotely sense tree species composition improves, it allows us to create more tailored models of the carbon cycle which incorporate not only climatic factors, but also biotic factors which govern productivity. We therefore need to understand how species composition and biodiversity metrics affect land-surface phenology.

In the deciduous woodlands of Zambia, a highly pronounced single wet-dry season annual oscillation is observed across the majority of land area, with local exceptions in some mountainous areas (). Variation in leaf phenological activity across the country has a large influence on annual gross primary productivity. Using Zambia as a case study, we can expect similar response from deciduous woodlands across southern Africa, with important consequences for the global carbon cycle ().

While cumulative leaf production across the growing season may be the most important aspect of leaf phenology for GPP, other phenological metrics may be more important for ecosystem function and habitat provision for wildlife. Periods of green-up and senescence which bookend the growing season are key times for invertebrate reproduction (), soil biotic activity () and herbivore browsing activity (). Pre-rainy season green-up in water-limited savannas provides a valuable source of moisture and nutrients before the rainy season, and can moderate the understorey microclimate, increasing humidity, reducing UV exposure, and moderating diurnal oscillations in temperature, reducing ecophysiological stress which can lead to mortality during the dry season. An increase in the time between leading tree growth and the onset of seasonal rains provides a buffer to stressful dry season climatic conditions and wildlife activity. A slower rate of green-up caused by tree species greening at different times provides an extended period of bud-burst, thus maintaining the important food source of nutrient rich young leaves for longer ().

In this study we contend that, across Zambian deciduous savannas, tree species diversity and composition influence three key measurable aspects of the tree phenological cycle: (1) the rates of greening and senescence at the start and end of the seasonal growth phase, (2) the overall length of the growth period, and (3) the lag time between green-up/senescence and the start/end of the rainy season. It is hypothesised that: (H₁) due to variation among species in minimum viable water availability for growth, plots with greater tree species richness will exhibit slower rates of greening and senescence as different species green-up and senesce at different times. We expect that: (H₂) in plots with greater species richness the start of the growing season will occur earlier in respect to the onset of rain due to an increased likelihood of containing a species which can green-up early, facilitating other species to initiate the growing season. We hypothesise that: (H₃) plots with greater species richness will exhibit a longer growth period and greater cumulative green-ness over the course of the growth period, due to a higher resilience to variation in water availability, acting as a buffer to ecosystem-level productivity. Finally, we hypothesise that: (H₄) irrespective of species diversity, variation in tree species composition and vegetation type will

83 cause variation in the phenological metrics outlined above.

84 2 Materials and methods

85 2.1 Data collection

86 We used plot-level data on tree species diversity across 709 sites from the Zambian Integrated
87 Land Use Assessment Phase II (ILUA-II), conducted in 2014 (Mukosha and Siampale, 2009; Pel-
88 letier et al., 2018). Each site consisted of four 20x50 m (0.2 ha) plots positioned in a square around
89 a central point, with a distance of 500 m between each plot (Figure 2). The original census con-
90 tained 993 sites, which was filtered in order to define study bounds and to ensure data quality.
91 Only sites with ≥ 50 stems ha^{-1} ≥ 10 cm DBH (Diameter at Breast Height) were included in the
92 analysis, to ensure all sites represented woody savanna rather than ‘grassy savanna’, which is con-
93 sidered a separate biome with very different species composition and ecosystem processes govern-
94 ing phenology (Parr et al., 2014). Sites in Mopane woodland were removed by filtering sites with
95 greater than 50% of individuals belonging to *Colophospermum mopane*, preserving only plots with
96 Zambesian tree savanna / woodland. To eliminate compositional outliers, plots with fewer than
97 five species with more than one individual were excluded. Plots dominated by non-native tree
98 species ($\geq 50\%$ of individuals), e.g. *Pinus* spp. and *Eucalyptus* spp. were also excluded, as these
99 species may exhibit non-seasonal patterns of leaf production ().

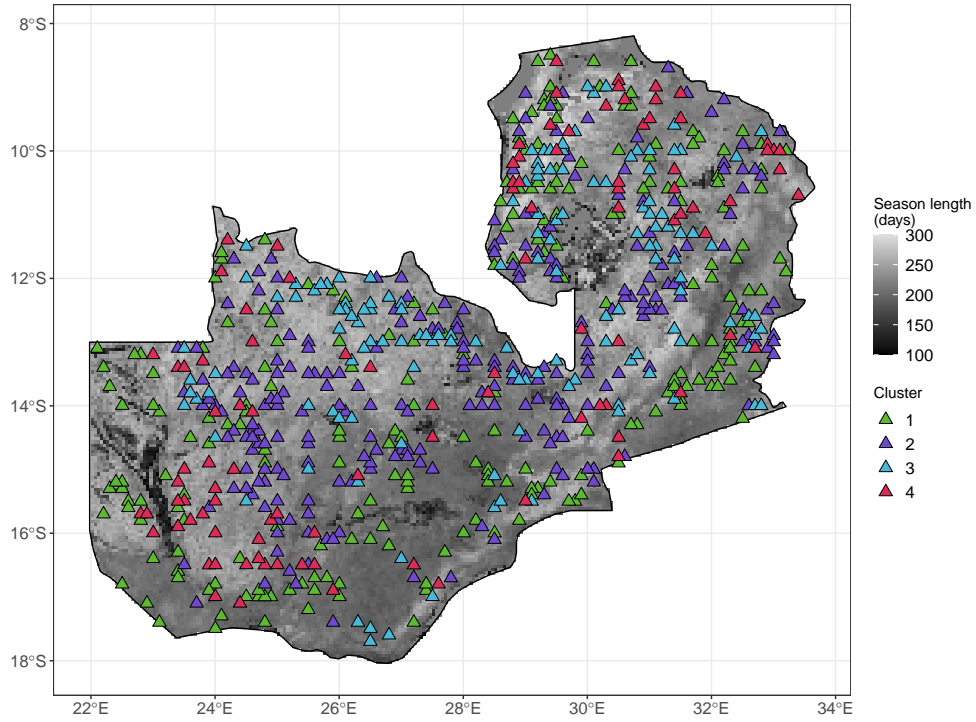

Figure 1: Distribution of study sites within Zambia as triangles, each consisting of four plots. Sites are coloured according to vegetation compositional cluster as identified by the PAM clustering algorithm on NSCA ordination axes of species abundance data. Zambia is shaded according to growing season length as estimated by the MODIS VIPPHEN-EVI2 product, at 0.05 degrees spatial resolution (Didan and Barreto, 2016).

Figure 2: Schematic diagram of plot layout within a site. Each 20x50 m (0.2 ha) plot is shaded grey. The site centre is denoted by a circle. Note that the plot dimensions are not to scale.

100 Within each plot, the species of all trees with at least one stem ≥ 10 cm DBH were recorded. Plot
101 data was aggregated to the site level for analyses to avoid pseudo-replication caused by the more
102 spatially coarse phenology data. Tree species composition varied little among the four plots within
103 a site, and were treated as representative of the woodland in the local area. Using the Bray-Curtis
104 dissimilarity index of species abundance data, we calculated that the mean pairwise compositional
105 distance between plots within a site was lower than the mean compositional distance across all
106 pairs of plots in 93.9% of cases.

107 To quantify phenology at each site, we used the MODIS MOD13Q1 satellite data product at 250
108 m resolution (Didan, 2015). The MOD13Q1 product provides an Enhanced Vegetation Index (EVI)
109 time series at 16 day intervals. EVI is widely used as a measure of vegetation growth, as an im-
110 provement to NDVI (Normalised Differential Vegetation Index), which tends to saturate at higher
111 values. EVI is well-correlated with gross primary productivity and so can act as a suitable proxy
112 (). We used all scenes from January 2015 to August 2020 with less than 20% cloud cover cover-
113 ing the study area. All sites were determined to have a single annual growth season according to
114 the MODIS VIPPHEN product (), which assigns pixels (0.05° , 5.55 km at equator) up to three
115 growth seasons per year. We stacked yearly data between 2015 and 2020 and fit a General Addi-
116 tive Model (GAM) to produce an average EVI curve. We estimated the start and end of the grow-
117 ing season using the first derivative of the GAM. We identified the start of the growing season as
118 the day where the slope of the curve first exceeds a slope of 0.05, which is maintained or exceeded
119 for 10 or more days and the end of the growing season as the last day where the slope of the curve
120 falls below -0.05, which has been maintained for 10 or more days. We estimated the length of the
121 growing season as the number of days between the start and end of the growing season defined as
122 above. We estimated the greening rate as the slope of a linear model across EVI values between
123 the start of the growing season and the point at which the slope of increase fell below 0.05. Simi-
124 larly the senescence rate was estimated as the slope of a linear model between the point where the
125 slope of decrease fell below -0.05 and the end of the growing season Figure 3.

126 Precipitation data was gathered using the “GPM IMERG Final Precipitation L3 1 day V06” dataset,
127 which has a pixel size of 0.1° (11.1 km at the equator) (**GPM**), between 2015 and 2020. Daily to-
128 tal precipitation was separated into two periods: precipitation during the growing season (growing
129 season precipitation), and precipitation in the 90 day period before the onset of the growing sea-
130 son (dry season precipitation). Similar to estimation of the growing season, the rainy season was
131 defined using the first derivative of a GAM to create a curve for each site using stacked yearly pre-
132 cipitation data. The slope coefficient used to identify the start and end of the rainy season was
133 0.06. Mean diurnal temperature range (Diurnal δT) was calculated as the mean of monthly tem-
134 perature range from the WorldClim database, using the BioClim variables, with a pixel size of 30
135 arc seconds (926 m at the equator) (Fick and Hijmans, 2017). averaged across all years of avail-
136 able data (1970-2000).

Figure 3: Example EVI time series, demonstrating the metrics derived from it. Thin black lines show the raw EVI time series, with one line for each annual growth season. The thick black line shows the GAM fit. The thin blue lines show the minima which bound the growing season. The red line shows the maximum EVI value reached within the growing season. The shaded cyan area of the GAM fit shows the growing season, as defined by the first derivative of the GAM curve. The two orange dashed lines are linear regressions predicting the greening rate and senescence rate at the start and end of the growing season, respectively. Note that while the raw EVI time series fluctuate greatly around the middle of the growing season, mostly due to cloud cover, the GAM fit effectively smooths this variation to estimate the average EVI during the mid-season period.

2.2 Data analysis

To quantify variation in tree species composition we used a Non-Symmetric Correspondence Analysis (NSCA), based on tree species abundance per site, with four axes (Inertia = 1.81), using the `ade4` R package (Dray and Dufour, 2007). The first 4 axes of the NSCA explained `nscaper` of the variation in species composition among sites according to eigenvalue analysis. We performed clustering on the NSCA axes, using the PAM (Partitioning Around Medoids) algorithm available in the `cluster` R package (Maechler et al., 2019). We identified four compositional groups based on this analysis which were used as random effects in statistical models. **More technical detail on NSCA procedure**

We specified multivariate linear models to assess the role of tree species diversity on each of the chosen phenological metrics. We defined tree species diversity using both species richness and abundance evenness as separate independent variables. Abundance evenness was calculated as the Shannon Equitability index ($E_{H'}$) (Smith1996) was calculated as the ratio of the Shannon diversity index to the natural log of species richness. We defined a maximal model structure including

tree species richness, abundance evenness, the interaction of species richness and vegetation type, and climatic variables shown by previous studies to strongly influence phenology. The quality of the maximal model was compared to models with different subsets of independent variables using the model log likelihood, AIC (Akaike Information Criteria), BIC (Bayesian Information Criteria), and adjusted R^2 values for each model. For each phenological metric, the best model according to the model quality statistics is reported in the results. All models were fitted using Maximum Likelihood to allow comparison of models (). Independent variables in each model were transformed to achieve normality where necessary and standardised to Z-scores prior to modelling to allow comparison of slope coefficients within a given model. All statistical analyses were conducted in R version 4.0.2 (R Core Team, 2020).

3 Results

Model selection showed that richness and evenness are important determinants of each phenological metric, across vegetation types Figure 4. Models predicting rainy season - growing season lags included only species and richness. It is striking that in models for green-up lag and season length, species richness and evenness had contrasting effects on these phenological metrics. Species richness increased the green-up lag time and increased season length, while evenness had the opposite effect.

Against expectations, tree species richness and evenness had negative effects on cumulative EVI, while wet season precipitation had a positive effect and diurnal temperature range had a negative effect, as expected. Despite this, species richness had a positive effect on season length.

Model estimates for both greening rate were poorly constrained, with wide confidence intervals on model coefficients which overlapped zero, indicating that other unmeasured drivers had important influence over these variables. The model for greening rate explained $<0.001\%$ of variance in the response variable. As expected, greening rate was negatively affected by species richness and abundance evenness. A higher species richness led to a slower rate of greening.

Interestingly, the best models for start of season and end of season lag time included only species richness and evenness as fixed effects. An increase in species richness led to an increase in the negative lag between the start of the growing season and the start of the rainy season, while the opposite was true for the lag between the end of the growing season and the end of the rainy season. For all phenological metrics, models including species richness and evenness were of better quality than those containing only climatic variables.

The slope of the relationship between species richness and phenological metrics varied among vegetation types, but largely maintained the same direction. Only in greening rate, senescence rate, and season length did vegetation types have differing slope estimates.

Cluster	Species	Indicator value
1	Diplorhynchus condylocarpon	0.256
1	Combretum molle	0.243
1	Combretum zeyheri	0.241
2	Julbernardia paniculata	0.568

4 Discussion

The ability for us now nearing to be able to remotely sense tree species diversity allows us to make more tailored models of the carbon cycle which incorporate not only climatic factors, but also biotic factors which govern productivity. We therefore need to understand how species composition and biodiversity metrics affect land-surface phenology.

5 Conclusion
